## Abstract

This paper presents a method for noise removal from hyperspectral data using wavelets. Normally, data collected in the field will contain several types of noise. One type is the small amount of noise that is superimposed along the signal. This noise will not degrade the characteristic shape of the signal, but will add a small systematic disturbance to it. This noise is usually caused by the physical instrument or field environment conditions. This noise, although small, can be troublesome in interpolating data. The natural growth in the understanding of wavelet applications now affords the capability to remove this noise without degrading the signal. A wavelet transform was applied to hyperspectral percent reflectance - wavelength data sets. The resulting power spectrum was filtered so that specific wavelet coefficients were removed. An inverse wavelet transform was then applied to this filtered spectrum to obtain a noise free data set.

**Key words:** Hyperspectral, noise removal, wavelets.

## Introduction

Hyperspectral data, at 5 - 10 nmeter bandwidth, has been used to conduct basic field and laboratory research to determine relations between earth surface components, targets, background characteristics, influencing climatic and meteorological conditions, and their patterned or spectral reflectance, luminance, and emittance values as recorded by airborne or satellite remote sensing systems. A number of products have been developed from these measurements including databases,

empirical and mathematical models, manual and digital image analysis paradigms, and specialized detection techniques for U.S. Army terrain information requirements, intelligence needs, targeting, and environmental applications. Research and exploratory development also has been conducted to identify new technologies and pursue new initiatives using hyperspectral remote sensing measurements together with interferometric synthetic aperture radar (IFSAR) information to enhance the Army's effectiveness in carrying out its land combat mission.

This effort was motivated by the desire to accurately interpolate hyperspectral reflectance measurements to one (1) nmeter from two (2) and five (5) nmeter field-collected data and to determine radiance or reflectance values at specific wavelengths. Before this can be achieved, noise in the data must be removed with the lowest probability that sharp signal features will become blurred, and spikes, jumps, and other non-smooth features will be unaffected. The natural growth in the understanding of wavelet applications now affords the capability to remove this noise without degrading the signal. Furthermore, ridding signals of noise often is much easier in the wavelet domain than in the original domain.

## De-noising Procedure

The de-noising procedure involves only three basic steps. First, the wavelet transform of the signal is taken; second, the wavelet coefficients in the transform are filtered in such a way that only those coefficients that correspond to the noise are removed from the wavelet transformed signal. The third step is to do an inverse wavelet transform to reconstruct the original signal, but without the noise. A fundamental understanding of the signal

characteristics is needed in advance of de-noising. It also should be understood that it is almost impossible to filter noise without affecting the signal [Strang & Nguyen 1996].

There are many different wavelets, and new ones are constantly being invented and developed. Before any noise removal takes place, the type of wavelet must be designed or selected from many that are available. This selection process can be complex involving the data type, time, and efficiency, among other factors. For hyperspectral data, as will be shown later, a number of wavelets do a very good job of noise removal.

The filtering of the coefficients works by selecting a threshold value and setting those wavelet coefficients that are below this value to zero (0). It could be argued that determining the threshold value is arbitrary or difficult, but much work has been done by others [Bruce et al, 1996] so that now there is little mystery about this value.

## Data

The data used in this effort was collected over the Yuma, Arizona desert during the months of July and August 1996 using a Geophysical Environmental Research Spectrometer. Table 1 shows a small sample of a data set of raw data collected. This particular target is a smooth plywood board. The percent reflectance was measured at wavelengths ( $\lambda$ ) of 300 to 1000  $\eta$ meters at regular two (2)  $\eta$ meter intervals. Figure 1 displays a plot of this data. The plot shows a small sine-wave-like disturbance along the signal. It is this disturbance that should be removed. These raw data were interpolated to one (1)  $\eta$ meter using a simple cubic spline. Table 2 shows the interpolated values. Note that these interpolated values are computed before any noise reduction routine is applied to the data.

A noise removal routine was applied to the raw data. The routine employs a Daubechies-4 wavelet. Figure 2 shows a plot of the data after noise has been removed. These noise-free data were interpolated to one (1)  $\eta$ meter using the

| 618                        | 29.3175             | 636                        | 29.9513             |

same cubic spline as before. Table 3 shows these interpolated values. The difference in the before and after noise removal interpolated values is not dramatic, but as can be seen from the comparison of the two plots, the sine-wave-like disturbance has been removed. Much resolution is lost in the reformatting of the plots, but the real-time plots clearly show the disturbance removed. Both plots were generated without the interpolated values. The largest difference between the raw and de-noised measured values is approximately  $\pm 0.5$  percent reflectance, and approximately  $\pm 1.0$  percent in the interpolated values. The significance and justification for the removal of such small amounts of noise is beyond the scope of this paper.

### Noise-Added Data

To better assess wavelet de-noising, a slightly different procedure was implemented with a different data set.

This second data set is the hyperspectral measurement of a camouflage net. A small amount of noise was added to the data to ascertain that the data are not noise free. Table 4 shows a small sample of these raw measurements. Note that these values are irregularly spaced and this data has to be resampled to regularly spaced values. The wavelet transform assumes evenly spaced data, however this data set is very close to being evenly spaced with not much error introduced. The spacing for these data are  $1.62 \pm 0.01$   $\mu\text{meters}$ . It should be understood that the spectrometer has a tolerance range in the collection of data. The data are recorded as being evenly spaced, however there is a very small variation in the measurement interval. Table 5 shows the resampled measurements with noise added.

Figure 2. De-noised Data (Smooth Plywood)

Figure 3. Raw & De-noised Data Plots (Camouflage Net)

Figure 4. All Wavelets Plot (Smooth Plywood)

The noise removal routine was applied to this resampled data. Figure 3 is a plot of the raw data and the noise-added data. The raw data were de-noised and then resampled to regularly spaced values. The difference in the values between de-noising first and then resampling, and resampling and then de-noising is very small, which is an indication that the irregular sampled data are close enough in the interval range to be treated as evenly sampled data.

This data set was de-noised using the same Daubechies-4 wavelet routine. It also was de-noised with Daubechies-6, Symmlet-6, Symmlet-8, Coiflet-2, Coiflet-3, and Haar wavelet routines. Figure 4 is a composite plot of all these data. All plots are within two (2) percent reflectance of each other, which

indicates that all of these wavelets do the same job for de-noising hyperspectral data. The only one plot that seems out of place is the Haar wavelet transform. The Haar wavelet produces a step function that was expected because of the very nature of the Haar wavelet. Of the seven wavelets used in this effort, Symmlet-8 appears to do a better job. The rationale for this statement is that when relatively noise-free raw data were plotted and noise was added to these data, and then the noise-added data were de-noised using the different wavelets, the resulting Symmlet-8 data were closer to the original data than the other wavelets. This procedure was performed only a few times therefore the results may not be conclusive. More analysis is needed.

## Conclusions

After analysis of the results it is concluded that wavelets are a viable tool for noise removal from hyperspectral data. There is no substitute

for a good measurement, however the times when data has to be interpolated or resampled, wavelets seem to provide a good solution. Many commercial software packages now include wavelet tools that make it easy to work with wavelets.
